SmartNIC-assisted Kernel-User Network Packet Zero-copying

Kernel-user data copying contributes one of the largest overheads in the network packet processing. I introduced a SmartNIC-based zero-copying framework utilizing Nvidia Bluefield-2. This system splits packet headers and payloads, storing them in separate memory regions. The header is processed through kernel network stack, while the payload is ‘zero-copied’ directly to user applications. By eliminating the copying overhead, we can significantly improve network performance.

Expedited Container Overlay Networks

Container overlay networks, compared to bare-metal host networks, experience performance degradation due to multiple asynchronous stages. Our development, ECON, streamlines this by having all packets in a flow follow a consistent path, bypassing non-critical processing stages after recognizing a flow’s ultimate destination. This approach has demonstrated improvements in container throughput by up to 121%, a reduction in average latency by up to 61%.

Streamlining Packet Processing with Flow Prioritization

In highly utilized systems, short-lived, latency-sensitive network flows can suffer from extended queuing delays due to the kernel network stack’s inability to differentiate packet performance needs. We proposed PRISM – an innovative in-kernel method, which identifies the packets’ priority early on and establishes a distinct, streamlined processing path for high-priority flows. As a result, we reduce latency for these flows by over 50% in heavily loaded systems.

Parallelizing Packet Processing at Packet-level

Even with state-of-the-art solutions like FALCON (device-level flow pipelining), a saturated single CPU core can still bottleneck a network flow. To address this, I developed MFLOW – a novel in-kernel packet-level steering technique. MFLOW evenly distributes a high-demand flow into several lightweight micro-flows across multiple CPU cores for parallel processing. Micro-benchmark tests reveal throughput improvements by 81% for TCP and 139% for UDP.

Pipelining Packet Processing at Device-level in Overlay Networks

Container overlay networks often underperform compared to host networks due to prolonged data processing paths. In response, I designed FALCON – a fast and balanced in-kernel solution that distributes the excessive software interrupts associated with various network devices onto multiple CPU cores for processing. Falcon enhances throughput by 300% for web serving applications and cuts tail latency by 53% for data caching applications.

Block-accessible Overlay File System for Container Storage

Overlay file systems often face extended write latencies as write operations on read-only container images require copying to a separate writable layer. Our solution, BAOVERLAY, is a block-accessible overlay file system that partitions files into fine-grained blocks, optimizing Copy-on-Write operations to involve only certain blocks instead of entire files. Tested with Linux Ext4 as the backing file system, BAOVERLAY markedly improved applications’ I/O performance with up to 32x faster performance for 1KB files and 64x faster for 4MB files.
